ABSTRACT
In order to prevent information retrieval (IR) and robotic process automation (RPA) tools from functioning improperly due to website evolution, it is important to develop web monitoring tools to monitor changes in a website and report them to the developers and testers. Existing monitoring tools commonly make use of DOM-tree based similarity and visual analysis between different versions of web pages. However, DOM-tree based similarity suffers are prone to false positives, since they cannot identify content-based changes (i.e., contents refreshed every time a web page is retrieved) and GUI widget evolution (e.g., moving a button). Such imprecision adversely affect IR tools or test scripts. To address this problem, we propose approach, WebEvo, that first performs DOM-based change detection, and then leverages historic pages to identify the regions that represent content-based changes, which can be safely ignored. Further, to identify refactoring changes that preserve semantics and appearances of GUI widgets, WebEvo adapts computer vision (CV) techniques to identify the mappings of the GUI widgets from the old web page to the new web page on an element-by-element basis. Empirical evaluations on 13 real-world websites from 9 popular categories demonstrate the superiority of WebEvo over the existing work that relies on DOM-tree based detection or whole-page visual comparison, while also being faster in visual analysis.

1 INTRODUCTION

With the development of web technology and the beginning of the Big Data era, websites have become increasingly rich with web content, which has led to the development of various technologies for extracting data from websites. Several Information Retrieval (IR) tools are constantly reading data from web pages and using them to power different applications. These tools depend on the location of the data to be extracted on a given web page. The common positioning techniques for elements in web pages include XPath (XML Path Language) positioning [43], CSS (Cascading Style Sheets) selector positioning [44], and other simple positioning techniques based on different attributes. In web applications, the elements on the web page are often changed due to requirements change or get displaced due to insertion or deletion of other elements. Such changes can cause these positioning techniques to fail to locate the elements to extract data from.

Additionally, web application testing tools [6] commonly use automated scripts to verify the proper functioning of web applications. Recently, robotic process automation (RPA) tools [41] that leverage automated scripts to automate the tasks in the Graphical User Interface (GUI) of web applications and other applications are also gaining attentions from industry [20, 42]. The automated scripts used by web testing and RPA automate manual operations performed on the web application’s GUI, such as sending click events, filling in and submitting forms etc. Despite their popularity, such tests and automated tasks are prone to failure due to simple structural changes in a web page. Researchers have identified web element locators to be the main reason for the failure of test scripts [15, 39]. Due to changes in a web page structure, elements on a web page can move to different locations within the page or get deleted, which can cause task failures, where the automated tasks fail to deliver their expected results, and test breakages - where the tests raise exceptions that do not reflect the presence of a bug.

As addressing these issues by manual maintenance is labor-intensive and time consuming, it is important to develop monitoring tools that can monitor web pages and automatically identify changes that can potentially stop IR tools and test scripts from functioning properly. Existing tools for monitoring web page changes,
commonly exploit the differences in the DOM structures of two different versions of the web page and apply visual analysis on test set executions. Considering only the differences in the DOM of web pages, such as in [15, 19], makes the techniques susceptible to high number of false positives as changes in the DOM structure of a web page (e.g., changes of weather values) may not break RPA tools or test scripts. The state-of-the-art web test repair tool Vista’s [39] leverages computer vision (CV) techniques to identify changed elements that preserve their appearances in new web pages, and repair test scripts to use the updated locators of the changed elements. Their adopted template-based matching technique [26, 36] compares the screenshots of whole web pages, which is also prone to false positives since the precision of the technique is greatly affected by background colors and the appearance of other web elements that are close to the changed elements.

Towards developing an automated tool for detecting changes, we identify two technical challenges.

1. The first challenge is determining the type of changes that can cause RPA tools or test scripts to break and identifying them on a web page. We note that there are two types of web page changes - content-based changes and semantic structure changes. We define content-based changes as web contents being constantly updated based on what a web server delivers to the client browser, such as stock prices, weather, and advertisements. This type of changes usually do not cause task failures as RPA tools typically locate these contents using their parent elements (e.g., the div that holds the weather), which remain unchanged. As opposed to content-based changes, semantic structure changes refer to element changes that alter the underlying structure of the web page. Such changes to a web page or parts of a web page are the root cause of element locators failing to find new locations of modified or deleted elements. An illustrated example is in Section 2.

2. The second challenge relates to using CV techniques to perform visual analysis on the web elements. Sometimes an evolved web page may move a link to a different location (e.g., moving to another div element) or change the structure and attributes of a textbox (e.g., updating the name attribute) but preserves its semantics and appearance. Such changes often result in the changes of the locators for these elements. It is important to map these changed elements to the original elements in the old web pages, so that RPA tools or test scripts that operate on the original elements can be automatically fixed by using the mappings. As the structures of the changed elements and the original elements are generally different, DOM-tree based techniques often consider the changed elements as new elements and cannot correctly identify the original elements in the old web page to identify the elements whose text and images are different across historic web pages as content-based changes. The content-based changes are then filtered from the candidate changed elements. To address the challenge 2, rather than analyzing the screenshots of whole web pages, WebEvo obtains the screenshots of the candidate changes and combines both text and image similarities to identify mappings between the original elements in old web pages and the changed elements in new web pages. In this way, our fine-grained analysis minimizes the noises brought by background and nearby elements by comparing the screenshots on an element-by-element basis, and the combination of text similarity and image similarity can correctly create mappings even if many elements in new web page have similar appearances.

WebEvo is evaluated on 13 real-world websites from 9 popular categories [2–4]. For each website, we choose a target web page, an evolved page, and three history pages to detect changed elements. Our results show that WebEvo is effective in detecting changed elements, achieving high precision (0.91), recall (0.79), and F1 values (0.84). We also compare the effectiveness of WebEvo against DOM-tree based detection [15, 19] and Vista [39], the state-of-the-art visual test repair tool. The results show that Vista is significantly more effective than the DOM-tree based detection, which achieves a F1 score of 0.50. As Vista cannot detect content-based changes, we compare WebEvo with Vista on whether they can correctly identify the mappings of the changed elements in the old and new web pages. The results show that Vista achieves a F1 score of 0.39, which is much worse than WebEvo. Such results demonstrate the superiority of WebEvo over the existing work that relies on DOM-tree based detection or whole-page visual comparison. Finally, we also compare the runtime performance of WebEvo and Vista, and the results show that WebEvo’s analysis time is 42.01% less than Vista’s on average. The tool and the results are available publicly at the project website [1].

Our paper makes the following contributions:

- The first technique that filters content-based changes and detects only semantic structure changes for evolving web pages.
- A novel technique that analyzes historic web pages to detect content-based changes.
- A novel semantics-based technique that combines both text similarity and image similarity to create mappings for the changed elements in new web pages.
- An empirical evaluation of WebEvo on 13 popular websites in identifying changed elements demonstrating higher detection and runtime performance.
2 MOTIVATING EXAMPLE

In this section, we present several examples that motivate the design of WebEvo to detect semantic structure changes, filter content-based changes, and identify mappings in new web pages using semantics-based visual search.

DOM-based Evolution. Browsers adopt the HTML Document Object Model (DOM) to organize and render the Graphic User Interfaces (GUIs) of web pages. DOM is based on XML, which represent GUI objects (e.g., buttons, hyper links, and text labels) as XML elements and the relationships among these elements as a tree (i.e., the hierarchy of XML elements). Based on the DOM hierarchy, XPath is used to find the location of any element on a webpage. As web application evolves, the changes of the GUIs will be reflected by the changes in DOM elements and the added/deleted/updated web elements can be identified by analyzing the DOM tree of the web pages. For example, in Figure 1, the old web page of www.w3schools.com at the top contains three hyper links in the banner, where the last link is "EXAMPLES" and its XPath locator is /html/body/div[4]/div/a[3]; the new web page at the bottom adds a new hyper link called "EXERCISES", and its XPath locator is /html/body/div[4]/div/a[4].

Consider another example web page of www.imdb.com shown in Figure 2. As shown in the highlighted areas, the new web page contains more social links, which use more images to represent the new links. While more links are used, the XPath for the web element that holds these links remains unchanged, being /html/body/div[3]/div/div[1]/div[2]/div[2]/ul/li[4].

Semantic Structure Changes. In web pages, many web elements are updated constantly due to different purposes such as weather, stock market indicator, news and advertisements. These changes usually are simple content-based changes, such as news headlines, articles and images being updated, which preserve the semantic structures of the web pages and thus will not cause problems for RPA tools or test scripts. On the other hand, there are changes that can alter the semantics expressed by certain parts of a web page. We refer to this type of changes as semantic structure changes.

Figure 4(a) shows the yahoo finance website from March, 2013, and Figure 4(b) shows the same web page from a few days later, where the contents - headlines, images, exchange rates - have changed but the semantic structure of the web page has remained the same. The content-based changes are highlighted within green rectangles. Finally, Figure 4(c) shows the evolved web page from November, 2013, where the currency ticker moving to the top of the page and being displayed horizontally (shown within the red rectangles), changing the semantics expressed by that part of the web page. Due to this change, a tool monitoring stock prices or exchange rates from the web page may no longer function as intended. Therefore, it is important to detect web element changes that change the semantic structure of a web page.

Mapping Elements in New Web Pages. Instead of DOM-based updates, the evolution of web elements may cause the locators of some elements used by RPA tools to be changed. As the DOM structures of these elements can be very different in new web pages, existing techniques [39] adapt computer vision techniques to detect similar images for detecting such changes. However, considering
only images may not be sufficient. For example, in Figure 3, the “LEARN W3.CSS” section in www.w3cschools.com has a new text content, and the “LEARN PHP” section changes the display of the text content from two lines to one line. If only image similarity is used to detect these changes, the changes will be considered as two new web elements are added, instead of one updated element (i.e., the “LEARN W3.CSS” section), resulting in inaccurate detection.

This inspired us to consider a synergy approach that first compares the text similarity followed by image similarity comparison, which could significantly improve the accuracy of finding the mappings for the changed web elements.

3 DESIGN OF WEBEVO

3.1 Overview

We illustrate the overview of WebEvo in Figure 5. Our approach consists of two main modules, namely, the Semantic Structure Change Detection module and the Semantic Visual Search module. In the first module, using old and new versions of a web page as inputs, we detect all changed web elements, then filter out content-based changes and output Semantic Structure Changes. This module first performs DOM-tree based Change Detection by comparing the DOM trees of two pages to find content-based changes and structural changes. Then the detected changes are further pruned via our History-based Semantic Structure Change Detection technique to output only semantic structure changes. Finally, these detected changes are used as input to our Semantics-based Visual Search module, which outputs the semantic structure changes with their mappings using content similarity analysis. Based on these web page change mappings, we extract the suggestions for making appropriate code modification for IR tools and test scripts.

3.2 Semantic Structure Change Detection

Our goal is to find semantic structure changes occurring between different versions of a web page as shown in Figure 4. WebEvo performs a two-step detection: DOM-tree Based Change Detection and History-based Semantic Structure Change Detection. The first step identifies corresponding subtrees between two versions of a web page to detect content-based changes and DOM-structure changes by comparing web element attributes. To filter out content-based changes, the second step utilizes a novel history-based technique to prune the content-based changes from the output of the previous step to preserve only semantic structure changes.

According to the functions of web pages, we divide them into two categories: content display category and content submission category. For both types of web pages, we extract the DOM tree of a old and new versions of a web page using the HTMLCleaner tool. The two DOM trees and the part to be detected in the form of XPath are given to the DOM-tree based change detection module as input.

3.2.1 DOM-tree Based Change detection. This module detects whether a part of the web page has changed by comparing the attributes and the structure of the corresponding DOM-trees. Given two DOM trees $T$ and $T'$, to determine how the structure of $T$ has changed with respect to $T'$, WebEvo adapts the idea of Levenshtein Edit Distance [35] to identify the minimum element changes that can convert $T$ to $T'$, where an element change can be adding, deleting, or updating a node. The definitions for adding and deleting changes are straightforward: When an element $e$ in $T$ cannot be found in $T'$, $e$ is considered as a deleting change; when an element $e'$ in $T'$ cannot be found in $T$, $e'$ is considered as an adding change. Detecting update changes requires more checks on the attributes, since an updated element that has the same ID attributes (i.e., $id$, $class$, and tag) and is dissimilar to the element in the old web page (i.e., preserving only a few attributes) usually represents new semantics, very likely to causes RPA tools or test scripts to fail. Based on our empirical observations, when an element is updated in the new web page, its ID attributes (i.e., $id$, $class$, and tag) are often preserved, and most of its child nodes are still the same. Thus, WebEvo considers an element $e$ as a candidate for an update change only if it can find another element that shares $e$’s ID attributes and have similar child nodes; otherwise, $e$ is considered a deleted node that cannot be found in the new web page.

Algorithm 1 shows how WebEvo compares two DOM trees $T$ and $T'$. WebEvo first extracts the body elements (i.e., $e$ and $e'$) from both the trees, and uses the recursive function $TreeDiff$ to compute the changes for the subtrees rooted at $e$ and $e'$ (Lines 1-3). $TreeDiff$ computes the minimum changes that can convert the child elements of $e$ to the child elements of $e'$ using the Levenshtein Edit Distance. Here, a child node of $e$ is considered to be identical with a child node of $e'$ if one of three ID attributes (i.e., $id$, $class$, and tag) have identical values. By applying the edit distance algorithm based on this change definition, WebEvo identifies the matched nodes from the child nodes of $e$ to the child nodes $e'$. For each pair $(n, n')$ of the matched nodes, if (1) $n$ and $n'$ has only one ID attribute that have the same values and (2) the tag names of $n$’s child nodes and $n'$’s child nodes have more than 30% different values, then $n$ and $n'$ are considered not similar enough, and a corresponding adding or deleting change is reported; otherwise, an update change is reported for the attributes of $n$ and $n'$ if any (Line 7), and a recursive call of $TreeDiff$ is applied to identify changes of the child nodes of $n$ and $n'$ (Line 8). For the child nodes of $e$ that WebEvo fail to find the matched nodes in $e'$’s child nodes, WebEvo reports adding changes and deleting changes correspondingly (Line 9).

3.2.2 History-based Semantic Structure Change Detection. The DOM-tree comparison step detects both content-based and semantic structural changes. However, differentiating content-based changes from
semantic structure changes are challenging. The indicators of semantic structure are different from one web page to another. For example, in Figure 4(a), both the Strings "Name" and "+0.10%" are text elements in DOM. But the change from “Name” to "Code" is regarded as a semantic structure change of the web page (because the type of information under “Name” is different from the type of information under "Price"), while the change from “+0.10%” to “-0.02%” is just a content-based change.

To address this challenge, we leverage an important insight that the history of the web page can reflect which elements of the web page present the structural information. Specifically, the structural elements such as “Currencies” and “Name” remain unchanged while content elements such as the numerical values change frequently. Based on this information, this module is able to detect the elements whose contents (i.e., text and images) change constantly across historic pages.

Algorithm 2: Detecting Content-based Changes

Input: DOM-Tree $t$, Historic DOM-Trees $H$
Output: Content-based Changes $C$
1 $e = t.get("/body");$
2 for $h \in H$ do
3   $e' = h.get("/body");$
4   $P, U = findMatchedNodes(e, e');$
5   $C.addAll(U);$ // record unmatched nodes
6   for $p \in P$ do
7     $findChanged(p[0], p[1], C);$ // recursive search
8 $return C;$

Algorithm 2 shows the details on detecting content-based changes using historic web pages. The algorithm receives the DOM tree of a web page $t$ and the DOM trees of its historic web pages $H$ as input, and compares $t$ with each DOM tree $h$ from $H$. The algorithm starts the comparison from the body elements of $t$ and $h$ (Lines 1-3). It invokes the function $findMatchedNodes$ to find all the matched nodes from $t$ and $h$ (Line 4): for each pair of matched nodes, the two subtrees rooted at the matched nodes must have the same structure and all nodes should have the same tag names. For the unmatched nodes in $t$, they are considered as content-based changes (Line 5). For each pair of matched nodes, the algorithm invokes the function $findChanged$ to check whether the texts and the images of the matched nodes are the same; if not, a content-based change is reported (Line 7). Note that $findChanged$ performs the search recursively on the child nodes of each matched nodes as well.

Finally, WebEvo combines the information from the steps of text analysis and graphical element analysis as features to map the old web page and the new web page. Using the features, WebEvo computes the similarity scores between two elements of a web page. Based on the similarity scores, the elements having the highest similarity are chosen for internal structure analysis to identify content-based changes.

3.3 Semantics-based Visual Search

As illustrated in Section 2, changed elements may update their locations in the web pages but preserve their semantics and appearance. If these elements are not correctly identified, they will be considered as deleted elements in the old web page and new elements in the new web page, losing the opportunities to fix RPA tools and test scripts. To address this problem, WebEvo computes both text similarity and image similarity of the elements in both the old and the new web pages to identify such changed elements.

Algorithm 3: Semantics-based Element Mapping

Input: Target Element $e$, Candidate Elements $C$
Output: Matched Element $c$
1 if $e$ has text then
2   $C' = max heap;$
3   for Candidate Element $c \in C$ do
4     $c.textSim = compareText(e.text, c.text);$
5     $C'.add(c);$ // sort based on $c.textSim$
6   while $C'$ is not empty do
7     $c = C'.pop();$
8     $sim = compareImage(e, c);$
9     if $sim == true$ then
10        $return c;$
11   else
12     for Candidate Element $c \in C$ do
13        $sim = compareImage(e, c);$
14        if $sim == true$ then
15           $return c;$

Semantics-based Element Mapping. Algorithm 3 shows the algorithm for semantics-based visual search. The algorithm accepts as input the output from the Changed Element Detection module. For each detected changed element $e$, the algorithm aims to find an element in the candidate elements $C$ in the new web page that has similar content as $e$’s content. The candidate elements are obtained
Algorithm 4: Image Similarity

**Input:** Element $a$, Element $b$  
**Output:** true/false

```
1 original = getPicSim(a, b); 
2 if original >= threshold, then return true; // return if original images can match 
3 else 
4     greyScale(a); // convert a to greyscale 
5     greyScale(b); // convert b to greyscale 
6     grey = getPicSim(a, b); 
7     if grey >= threshold, then return true; // if images can match after greyscale 
8     else 
9         invertColor(b); // invert the colors of b 
10        if getPicSim(a, b) >= threshold, then return true; // images can match after inversion 
11        return false; // cases above all fails 
```

and color inversion [40] (Lines 11-13), to mitigate the color evolution problem. For some elements, grey scale conversion may not be effective to improve similarity computation. As these elements use black and grey colors, grey scale conversion will not help. To address this problem, WebEvo applies color inversion (Line 11) to invert the colors of the element and compute the similarity on the mutated image.

4 EVALUATION

We implement WebEvo upon Selenium [6] to locate web elements and take screenshots of web elements, and upon OpenCV [40] to mutate the collected screenshots and compute image similarity. We evaluate WebEvo on the web pages of 10 real-world web applications for identifying changed elements. Specifically, we aim to answer the following research questions:

- **RQ1:** How effective is WebEvo in identifying changed elements in web pages, compared to the state-of-the-art visual web repair approach, Vista [39]?
- **RQ2:** How effective can the changed content identification and semantics-based visual search be in improving WebEvo’s effectiveness?
- **RQ3:** What is the runtime performance of WebEvo, compared to Vista?
- **RQ4:** How effective is WebEvo in detecting changed elements that affect RPA and IR tools?

4.1 Subjects and Evaluation Setup

We collect popular web pages from the representative web applications in most popular categories [2–4] (e.g., e-commerce, entertainment, business, and job) as our evaluation subjects. These websites provide daily services to meet various needs of users and have great values for RPA tools to automate the process in these websites. For each chosen web applications, we aim to collect a target page, an evolved page, and three history pages to detect changed elements. To find web applications that meet these rules, we made use of Wayback Machine [10] that archives history of web pages of popular websites. To ensure that the collected web pages will have
A changed element can be a new element, a deleted element, or an updated element. For each reported detected changed element, we groundtruth the changed elements for each collected web page. To measure the effectiveness of WebEvo, we perform a two-step inspection: ○ we first applied the DOM-tree based detection of WebEvo on both the target and the evolved web pages to identify the changed elements, and then manually inspect each of them to confirm whether they are indeed changed in the new web page; ○ as the DOM-tree based detection may miss some changed elements, we further render the target and the evolved web pages and manually inspect each element of the target web page to confirm whether they are changed in the new web page. By combining the results of ○ and ○, we can obtain the groundtruth of the changed elements for each collected web application.

* Results of Vista consider only deleted and updated elements since Vista cannot handle added elements.

A substantial amount of changed elements for evaluations, we select web applications to collect web pages based on two rules. First, the web applications should be popular and their web pages should contain a large number of elements. This will rule out simple web pages with a few web elements such as www.google.com. Second, for the web pages on different dates, there should be at least 20 changed elements that belong to different element types (e.g., , , and ). As redesigning a whole web site requires users to spend more efforts in using the new web site, web sites do not tend to revamp the whole web site within a short period, but adopt a light-weight and progressive approach to upgrade the web sites [5, 7]. Thus, for each web site, we choose a target web page at a date and an evolved web page at a later date, and the average differences between these two dates are more than 2 years.

In total, we obtain 13 websites whose changed elements are above 20. For each web page, we used Chrome browser’s built-in function to capture the screenshot of the whole page, which can be used for changed element detection. Table 1 shows the details of the web applications and the collected web pages for the real-world dataset. Column “Website” shows the web sites from which we collect the web pages and Column “Category” shows which popular categories the web sites belong to. Column “# Elements” shows the number of web elements (e.g., , , and ) for a page and Column “LOC” shows the lines of HTML code in the page. Column “Collected Date” shows the dates for the collected history pages, target pages, and the evolved pages.

Groundtruth of The Changed Elements. For each collected web application, we perform a two-step inspection: ○ we first applied the DOM-tree based detection of WebEvo on both the target and the evolved web pages to identify the changed elements, and then manually inspect each of them to confirm whether they are indeed changed in the new web page; ○ as the DOM-tree based detection may miss some changed elements, we further render the target and the evolved web pages and manually inspect each element of the target web page to confirm whether they are changed in the new web page. By combining the results of ○ and ○, we can obtain the groundtruth of the changed elements for each collected web application.

Metrics. To measure the effectiveness of WebEvo, we compute the precision, recall, and values for the detected changed elements. A changed element can be a new element, a deleted element, or an updated element. For each reported detected changed element, we
We compared web pages. For fair comparison, we compare Vista XPath in the target web page as input and cannot effectively detect changes, otherwise, if an element changes and WebEvo changes. Based on these values, we compute the precision using $\frac{TP}{TP+FP}$, the recall using $\frac{TP}{TP+FN}$, and the F1 score using $2 \cdot \frac{prec \cdot rec}{prec + rec}$.

4.2 RQ1 Overall Effectiveness

We compared WebEvo with DOM-tree based detection, and Vista [39], a state-of-the-art visual web repair approach that automatically fixes web tests by finding changed elements. We implemented a DOM-tree based detection tool on the algorithm described in Section 3.2.1. This detection tool adopts the same idea as the existing work [15, 19], which compares the attributes and the structures of DOM trees to detect changed elements. As Vista provides a released tool, we directly used it for comparison. We applied the DOM-tree based detection tool, Vista, and WebEvo on the 14 websites and compare their effectiveness. We compare WebEvo with the DOM-tree based detection tool in detecting the added, detected, and updated elements. Note that Vista receives a locator (i.e., an XPath) in the target web page as input and cannot effectively detect new elements in the evolved page, since the locators of the new elements only exist in the evolved web page. Also, Vista cannot detect content-based changes as it lacks the capabilities to analyze historic web pages. For fair comparison, we compare WebEvo with Vista in detecting only the deleted and the updated elements without the detected content-based changes.

Comparison with DOM-based Detection. Table 3 shows the comparison results of WebEvo and the DOM-tree based detection tool, and Table 2 shows the comparison results of WebEvo and Vista. Overall, WebEvo effectively identifies changed elements in the websites with high precision (0.91), recall (0.79), and F1 values (0.84), while the DOM-tree based detection tool achieves low precision (0.40), recall (0.72), and F1 values (0.50). That is, WebEvo achieves a significant improvement (8.0% for F1 score) over the DOM-tree based detection tool. These results demonstrate that by combining DOM-tree based detection and semantics-based visual search, WebEvo effectively identifies not only new or deleted elements, but also updated elements that have property or location changes.

4.3 RQ2 WebEvo’s Novel Techniques

To evaluate the effectiveness of changed element detection and semantics-based visual search, we compare the detected changed elements for the web pages with and without using the semantics-based visual search. The results are shown in Table 3. Column “# Changed Elements” shows the number of changed element for each target page of the web applications. Column “WebEvo w/o visual search” shows the precision, recall, and F1 values without using

semantics-based visual search. As we can see, the precision, recall, and F₁ values drop to 0.58, 0.72, and 0.64 without using semantics-based visual search. That is, semantics-based visual search achieves 31.2% improvement for the F₁ score, which is a substantial improvement. Also, on average there are 40 detected content-based changes for each web page, which are related to weather, advertisement, news, and so on. Without filtering these content-based changes, the precision of the detected changed elements will further drop to 0.40 from 0.58, which demonstrates the effectiveness of detecting content-based changes.

4.4 RQ3 Runtime Performance

We measure the runtime performance of WEBEVO and compare with VISTA. As DOM-tree based analysis and history-based semantic structure change detection require only a few seconds to run, we mainly compare the runtime performance of both tools’ visual analysis. Table 4 shows the average analysis time for each changed element in our evaluations. On average, to finish the analysis, WEBEVO requires 42.01% less time than VISTA (37.04s vs. 63.92s). Also, WEBEVO is more efficient than VISTA in every website. This shows that applying CV techniques to compare whole web pages require significantly more time than element-by-element comparison.

4.5 RQ4 Detecting RPA and IR Breakages

We evaluate the effectiveness WEBEVO to detect web change elements that can prevent RPA and IR bots from executing their tasks. For different types of elements, we base our evaluation on determining the percentage of changed elements that are detected. Table 5 lists 11 websites where we found element changes through manual inspection that could break RPA and IR tools. For each website, we noted how many element changes were detected by WEBEVO for each element type that were changed, categorized by breakage type. Combining all the changed elements across all the websites with RPA breakages, WEBEVO detected 65% of the changes. For IR breakages, WEBEVO detected 100% of the changes. Most undetected changes can be attributed to WEBEVO’s detection not being granular enough. One such example is shown in Fig 9, where two <a> elements (within red rectangles) have changed, but instead of detecting those two changes, WEBEVO reports the container <div> (green rectangle) element as changed.

5 DISCUSSION

Content-based Changes. WEBEVO detects content-based changes by checking the texts and images across historic web pages. Our evaluation shows the effectiveness of the detection and how it reduces the false positives of WEBEVO. However, it is possible that some websites rename image files, give the same file names to different images, or use same texts for a couple of days in the content

related from web servers, which will cause WebEvo to produce false positives and false negatives. Even though we mitigate such issue by collecting historic web pages within a period, this issue can be further addressed by employing CV techniques to further compare the image similarity and checking more attributes when the text remains the same. Alternatively, if we can obtain the server code, which is not the assumption for this work, we may perform static analysis to identify elements whose contents are constantly changed based on the server output.

**Semantics-based Visual Search.** Our semantics-based visual search finds matching elements using the string similarity based on the Levenshtein distance [35] and the image similarity based on fingerprint. While the evaluations show promising results, the string similarity may miss synonyms that have low string similarity but high semantic similarity. This may be improved by combining string similarity with semantic similarity such as sentence similarity [8, 25] or semantic patterns [34, 38, 45]. WebEvo computes image similarity by hashing images into bit sequences and comparing the similarity of the bit sequence [21, 48]. This may not always produce desirable results due to the limitations of the hashing functions and could be improved by using object recognition such as SIFT/FAST [26, 27, 36]. Additionally, the synergy of string similarity and image similarity adopted by WebEvo may be replaced with deep learning techniques that models the joint semantics of text and images [18, 23, 24, 37].

**Threats to Validity.** The main internal threat comes from the mistakes we may make during changed elements labeling for each website used in our evaluations. To reduce the threat, each changed element is verified by at least two authors. We further check the HTML code and when we are not sure which changed elements cause the UI changes we use tools (e.g., chrome) to identify the corresponding UI parts for the changed elements. There are two main external threats to validity. First, we recognized the need to tailor WebEvo to different types of web pages to get effective outcome. Thus, we choose the representative websites in most popular categories and make sure that the old and the new web pages have non-trivial changes in terms of elements. Second, WebEvo performs comparison on the predefined attributes or tags to detect changed elements, which works well given that HTML rarely introduces new types of elements. WebEvo can be easily extended to support more types of web element by expanding the predefined list.

6 RELATED WORK

**Web Test Repair.** WATER [15] runs a web test, collects the DOM properties about the test breakages, and computes the similarity of the DOM properties for web elements to repair the tests. Built upon WATER, WATERFALL [19] repairs test breakages in the intermediate minor versions between two major releases of a web application. By using computer vision techniques, Vista [39] achieves better performance than WATER in repairing web tests. While WebEvo also uses computer vision techniques, WebEvo uses a finer grained visual information (i.e., the screenshot of an element versus the screenshot of the whole web page) and text semantics to improve the visual search of web elements, and our evaluations have shown the superiority of WebEvo over Vista.

**Web Application Repair.** Besides changes due to web application evolution, there are other unexpected changes of web elements that may cause problems. Mahajan et al. [29] propose automated repair techniques to address presentation changes when using different browsers. Their later work [9, 28, 30] also propose repair techniques to address mobile-friendly problems and internationalization problems in web applications. Cassius [33] and its extension VizAssert [32] provide an extensible framework for reasoning about web pages’ layout and can be used to repair faulty CSS in web applications. While these repair techniques are related to WebEvo in terms of detecting inconsistent web elements across different web pages, WebEvo focuses on detecting changed elements (i.e., new, deleted, and updated elements) and these techniques focus on the same web elements that have unexpected presentations under different settings.

**Computer Vision Techniques for Software Engineering Tasks.** REMAUI [31] adapts computer vision techniques for reverse engineering UIs of mobile apps. Sikuli [12, 47] identifies and controls UI components for automating UI testing via image recognition. WebDiff [14] and XPERT [13] identify visual differences using computer vision techniques, aim to detect cross browser rendering issues. IconIntent [46] collects a set of icons that represent sensitive data and uses computer vision techniques to determine whether the icons used by UI widgets are similar to the collected sensitive icons in Android apps. Besides computer vision techniques, WebEvo analyses web pages collected at different timestamps to identify changed contents, and further applies text similarity to choose
candidate web element for finding the mappings across different versions of the web pages.

DOM Tree-based Web App Analysis. The DOM structure-based methods typically parse the target and the evolved web page into a DOM tree and then uses an algorithm to calculate the similarity between the trees to find the subtree in the evolved version of the DOM tree that is closest to the target subtree structure of the target version. Flesca et al. proposed a subtree similarity comparison approach using a bipartite graph based maximum matching algorithm [17]. A node signature comparison algorithm to find textual changes in the DOM trees of the target and evolved web pages is presented in [22]. However, the general complexity of the tree similarity calculation method is relatively high and the overall performance is not high under the trend of increasingly complicated web pages. The results obtained based on only DOM information are also not accurate.

Machine Learning-based Web App Analysis. Machine learning based approaches extract the characteristics of web pages by analyzing a large number of web pages to classify various web pages. Each category of web pages is considered to have similar data extraction methods. Through this machine learning method, when the page changes, only a new analysis of the new version of the web page is required to automatically generate a new data extraction tool. Borgolte et al. presented an approach combining DOM-based comparison and clustering techniques to detect relevant changes on web pages [11]. However, machine learning approaches require the support of a large amount of data and has high requirements on the computational power of the device.

7 CONCLUSION

We have presented a novel framework, WebEvo, for monitoring web element changes that can break IR tools and web test scripts. Our tool performs DOM-based comparison between old and new versions of a web page and carries out novel non-content change detection using semantic and graphical analysis to filter out irrelevant changes and finally, a novel semantics-based visual search technique is used to refine the detected changes. We showed WebEvo’s practicality by evaluating our approach on datasets constructed from popular real-world websites and demonstrating substantially better detection and runtime performances. We also showed how WebEvo can detect breakages for IR and RPA tools.
